(54) Title: MICROINJECTION OF CRYOPROTECTANTS FOR PRESERVATION OF CELLS

(57) Abstract: A preservation method for biological material having cell membranes includes microinjecting the cells with sugar; preparing the cells for storage; storing the biological material; and recovering the stored biological material from storage. Carbohydrate sugars such as trehalose, sucrose, fructose, dextran, and raffinose, may be used as bio-protective agents.

WO 01/87062 A2

MICROINJECTION OF CRYOPROTECTANTS
FOR PRESERVATION OF CELLS

FIELD OF THE INVENTION

The present invention relates to the preservation of biological tissue using microinjection of intracellular protective agents containing sugar to preserve cells by freezing and/or drying.

BACKGROUND OF THE INVENTION

In recent years, chemotherapy and radiation therapy of patients with cancer has been increasingly successful and sustained remissions have been achieved.

However, the chronic side effects of these therapies to the reproductive systems of long-term survivors is of particular concern. These effects for women include depletion of ovarian germ cells and sterility. Due to the potential loss of future fertility of those exposed to cancer therapy, a need for oocyte banking has developed. Oocyte freezing, when combined with *in vitro* fertilization, may be beneficial to women desiring future fertility who are anticipating loss of gonadal function from extirpative therapy, radiation, or chemotherapy. Oocyte freezing may also provide a possible alternative to human embryo freezing, thus avoiding many of the legal and ethical problems encountered in embryo freezing.

The first successful cryopreservation of human embryos was achieved in 1983 and embryo freezing is now a routine procedure. In contrast, very limited success has been reported with cryopreservation of human oocytes. Only five successful pregnancies have been reported with more than 1500 cryopreserved oocytes. Therefore, the current methods of freezing are still considered

experimental and novel approaches are needed to overcome the difficulty encountered by cryopreservation of the human oocyte.

Traditional cryopreservation techniques include penetrating cryoprotectants at concentrations of 1 to 2M with, for example, dimethyl sulfoxide (DMSO),
5 glycerol, or ethylene glycol, followed by a slow freezing rate (0.3 to 0.5°C/min). Typically, oocytes are damaged due to long-term exposure to deleterious freezing conditions, including excessive dehydration and high electrolyte concentrations. An alternative approach, called vitrification (i.e. formation of glassy material without crystallization of ice, uses high concentrations of cryoprotectant mixtures
10 (6 to 8M) followed by rapid cooling in order to avoid the lethal effects of freezing on oocytes.

Though an attractive alternative, vitrification procedures suffer from the toxic and osmotic effects of high cryoprotectant concentration on sensitive cells. Neither of these two approaches (slow freeze-thaw and rapid vitrification) has
15 resulted in a reliably successful outcome for cryopreservation of human oocytes. Thus, there is a need for a reliable technique for human oocyte storage. In order to provide the preservation of mammalian cells necessary for application of living cells as a therapeutic tool in clinical medical care, new protocols for preserving living nucleated cells using low levels of non-toxic preservation agents and having
20 simple procedures applicable to a variety of cells must be developed.

SUMMARY OF THE INVENTION

The purpose of the present invention is to allow the storage of living cells in a dormant state and the subsequent recovery of the cells to an active state. This
25 method involves microinjecting into the cytoplasm of a cell a protective agent that is substantially non-permeating with respect to mammalian cell membranes and that maintains the viability of the cell such that it can be stored in a temporarily dormant state and substantially restored to an active state. The microinjected cell is

subjected to conditions that cause it to enter a dormant state and is stored in this dormant state. The stored cell can be subsequently restored to an active state. This method has the advantage of allowing any mammalian cell to be stored until it is needed under conditions that cause minimal, if any, adverse side-effects in the cell.

5 Thus, the invention, in some embodiments, provides a method for preserving living cells that begins with microinjecting a protective agent containing an effective sugar into the cell, preferably an oocyte. Other preferred cells that may be preserved include differentiated cells, such as epithelial cells, neural cells, epidermal cells, keratinocytes, hematopoietic cells, melanocytes, chondrocytes,
10 B-cells, T-cells, erythrocytes, macrophages, monocytes, fibroblasts, or muscle cells; and undifferentiated cells, such as embryonic, mesenchymal, or adult stem cells. In one preferred embodiment, the differentiated cells remain differentiated after they are recovered from a frozen or dried state, and the undifferentiated cells remain undifferentiated after they are recovered. The cells can be haploid (DNA content of
15 n; where "n" is the number of chromosomes found in the normal haploid chromosomes set of a mammal of a particular genus or species), diploid (2n), or tetraploid (4n). Other cells include those from the bladder, brain, esophagus, fallopian tube, heart, intestines, gallbladder, kidney, liver, lung, ovaries, pancreas, prostate, spinal cord, spleen, stomach, testes, thymus, thyroid, trachea, ureter,
20 urethra, or uterus. The cells may be from a human or non-human mammal, such as a monkey, ape, cow, sheep, big-horn sheep, goat, buffalo, antelope, oxen, horse, donkey, mule, deer, elk, caribou, water buffalo, camel, llama, alpaca, rabbit, pig, mouse, rat, guinea pig, hamster, dog, or cat.

 The method of the invention may advantageously use low levels, less than or
25 equal to about 6, 5, 4, 3, 2, or 1 M, or even less than about 0.4 M of preservation agent, and may use a sugar alone as the preservation agent, or sugar in combination with a conventional cryoprotectant, or in combination with other intracellular sugars or extracellular sugars. More preferably, the cytoplasmic concentration of

the sugars is less than 0.3, 0.2, 0.1, 0.05, or 0.01 M after microinjection and before freezing or drying of the cell. The extracellular concentration of the sugars is preferably less than 0.3, 0.2, 0.1, 0.05, or 0.01 M after dilution into a liquid medium containing the cell. If the cell is grown on a solid support, such as an agar plate, the concentration of the sugars in the preservation agent that is contacted with the cell is preferably less than 0.3, 0.2, 0.1, 0.05, or 0.01 M. In other preferred embodiments, the final concentration of extracellular sugar in the medium containing the cell is at least 2, 3, 4, 5, or 10-fold greater than the cytoplasmic concentration of intracellular sugar after microinjection and before freezing or drying of the cell. The intracellular and extracellular preservation agents may be the same or different molecular species.

Preferred protective agents include sugars such as monosaccharides, disaccharides, and other oligosaccharides. Preferably, the agent is substantially non-permeable such that at least 50, 60, 70, 80, 90, or 95% of the agent does not migrate across the plasma membrane into or out of the cell, by active or passive diffusion. Preferred sugars have a glass transition temperature of the maximally freeze-concentrated solution (T_g') that is at least -60, -50, -40, -30, -20, -10, or 0°C. Examples of such sugars are those listed in FIG. 8. The T_g' of other sugars may be routinely determined using standard methods such as those described by Levine and Slade (J. Chem. Soc., Faraday Trans. 1, 84:2619-2633, 1988). The sugar or conventional cryoprotectant with a T_g' below -50°C can be combined with a sugar with a T_g' above -50°C such that the resulting mixture has a T_g' of at least -60, -50, -40, -30, -20, -10, or 0°C, and this mixture is used for cryopreservation.

Suitable monosaccharides include those that have an aldehyde group (*i.e.*, aldoses) or a keto group (*i.e.*, ketoses). Monosaccharides may be linear or cyclic, and they may exist in a variety of conformations. Other sugars include those that have been modified (*e.g.*, wherein one or more of the hydroxyl groups are replaced with halogen, alkoxy moieties, aliphatic groups, or are functionalized as ethers,

esters, amines, or carboxylic acids). Examples of modified sugars include α - or β -glycosides such as methyl α -D-glucopyranoside or methyl β -D-glucopyranoside; N-glycosylamines; N-glycosides; D-gluconic acid; D-glucosamine; D-galactosamine; and N-acetyl-D-glucosamine. In other preferred embodiments, the preservation agent is an oligosaccharide that includes at least 10, 25, 50, 75, 100, 250, 500, 1000, or more monomers. The oligosaccharide may consist of identical monomers or a combination of different monomers. Other suitable oligosaccharides include hydroxyl ethyl starch, dextran, cellulose, cellobiose, and glucose. Other suitable preservation agents include compounds that contain a sugar moiety and that may be hydrolytically cleaved to produce a sugar. Still other suitable preservation agents include glycoproteins and glycolipids, which preferably have been modified by the addition of 1, 2, 3, 4, 5 or more sugar moieties derived from sugars with a Tg' of at least -60, -50, -40, -30, -20, -10, or 0°C or with a molecular weight of at least 120 daltons. By "sugar moiety" is meant a protective sugar that includes a group that can be bonded to another compound. For example, a reactive group--such as an alcohol, primary amine, or secondary amine--in a sugar can react with a compound, forming a product that includes the sugar moiety.

Another suitable extracellular preservation agent is a lectin or any protein that can non-covalently or covalently bind to a sugar that forms part of a cell-surface glycoprotein or glycolipid. This binding may stabilize the cellular membrane during storage of the cell.

Examples of other cyroprotectants that may be used in the methods of the present invention include sugars, polyols, glycosides, polymers, and soluble proteins with a molecular weight of at least 120 daltons. As illustrated in Figs. 8 and 9, compounds with higher molecular weights tend to promote glass formation at a higher temperature than that promoted by smaller compounds, allowing the cells to be stored at a higher storage temperature.

After treatment with the microinjected protective agent and, optionally, the external protective agent, the cell is then prepared for storage. In general, the cell may be prepared for storage by freezing and/or drying. Plunge freezing, vacuum drying, air drying, as well as freeze drying techniques may be employed. Typically, 5 oocytes are cooled at a rate of 0.1 to 10°C/min, preferably, between 0.3 and 5°C/min, and, more preferably, between 0.5 and 2°C/min, inclusive. Somatic cells are cooled at a rate between 0.1 and 200°C/min, preferably, between 0.5 and 100°C/min, and, more preferably, between 1 and 10°C/min or 10 and 50°C/min, inclusive. The cells are cooled to a final temperature of at least -60, -50, -40, -30, - 10 20, -10, 0, 10, or 20 °C (in order of increasing preference). In another preferred embodiment, the preservation agent inhibits or prevents the nucleation or growth of intracellular ice during freezing of the cells.

Extracellular preservation agents may reduce the osmotic shock to the cells that potentially results from the addition of an intracellular preservation agent. 15 Additionally, extracellular preservation agents may stabilize plasma membranes and provide mechanical strength to the cells during freezing or drying.

Once the cell is prepared for storage, it is stored in a manner appropriate to its preparation. Frozen cells can be stored at cryogenic temperatures and dried cells can be dry stored at ambient or other temperatures as appropriate. Recovery of 20 stored cells is geared to the method of their preparation for storage. Dried cells are rehydrated, and frozen cells are thawed. Preferably, at least 25, 35, 50, 60, 70, 80, 90, 95, or 100% of the recovered cells are viable. Cell viability may be measured using any standard assay, such as a "live/dead" assay using the green dye calcein-AM to indicate viable cells and the red dye ethidium homodimer to indicate dead 25 cells, according to the manufacturer's protocol (Molecular Probes, Inc.). In another preferred embodiment, at least 5, 10, 15, 25, 35, 50, 60, 70, 80, 90, or 95% of the recovered oocytes may be fertilized using standard *in vitro* fertilization techniques (see, for example, Summers *et al.*, Biol. Reprod. 53:431-437, 1995). Preferably,

the fertilized oocytes develop into 2-cell stage embryos, 4-cell stage embryos, morula-stage embryos, blastocyst-stage embryos, fetal-stage embryos, or viable offspring.

By "embryo" is meant a developing cell mass that has not implanted into the uterine membrane of a maternal host. Hence, the term "embryo" may refer to a fertilized oocyte, a pre-blastocyst stage developing cell mass, or any other developing cell mass that is at a stage of development prior to implantation into the uterine membrane of a maternal host and prior to formation of a genital ridge. An embryo may represent multiple stages of cell development. For example, a one cell embryo can be referred to as a zygote; a solid spherical mass of cells resulting from a cleaved embryo can be referred to as a morula, and an embryo having a blastocoel can be referred to as a blastocyst.

By "fetus" or "fetal" is meant a developing cell mass that has implanted into the uterine membrane of a maternal host. A fetus may have defining features such as a genital ridge which is easily identified by a person of ordinary skill in the art.

In another aspect, the invention provides a method of culturing mammalian cells *in vitro* by incubating the cells in a hypertonic media having an osmolarity of greater than 300, 310, 320, 330, 340, 350, 360, 370, 380, or more mosm. Preferably, the media includes one or more of the components listed in FIG. 7 or one or more cryopreservation agents of the present invention. Preferably, the media contains nutrients such as amino acids, sugars, lactate, or pyruvate. This media may be used to culture any mammalian cell, including the preferred cells listed above. In various preferred embodiments, this media is used to culture cells before, during, or after cryopreservation.

The present invention provides a number of advantages related to the cryopreservation of cells. For example, these methods may be generally applied to the preservation of any cell from any mammal. These cells may be stored in a frozen or dried state for any length of time until they are needed. Additionally, these cryopreservation methods involve the use of relatively low concentrations of

non-toxic preservation agents that cause minimal, if any, adverse side-effects in the stored cells. Moreover, the preservation agents reduce or eliminate the formation of intracellular ice during freezing which would otherwise damage the cells. If desired, both intracellular and extracellular preservation agents may be used to reduce the osmotic pressure caused by the addition of an intracellular preservation agent to the cells. Extracellular preservation agents may also stabilize plasma membranes and provide mechanical strength to the cells during freezing or drying. Furthermore, the present invention may enable a higher storage temperature (preferably, greater than -60°C) compared to conventional cryoprotectants (typically less than -80°C) due to the high 'Tg' of sugars.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will be more fully understood from the following detailed description taken in conjunction with the accompanying drawings, in which:

15

FIG. 1 is a flow chart showing steps in the method of the invention.

FIG. 2 is a schematic flow diagram listing one embodiment of the cryopreservation protocol of the present invention. This protocol may be modified by one skilled in the art for the preservation of other cells using other cryopreservation agents, cooling rates, dilution steps, and media.

20

FIG. 3A is a graph showing the volume of mouse oocytes in isotonic DMEM/F-12 medium prior to microinjection, DMEM/F-12 with 0.1 M extracellular trehalose (hypertonic medium) prior to microinjection, and DMEM/F-12 with 0.1 M extracellular trehalose (hypertonic medium) after microinjection of 0.1 M trehalose. Figs. 3B-3D are phase-contrast microscopy pictures of the oocytes under each of the three conditions listed above.

25

Figs. 4A-4D are bright-field microscopy pictures of human oocytes in isotonic DMEM/F-12 medium prior to microinjection, DMEM/F-12 with 0.15 M extracellular trehalose (hypertonic medium) prior to microinjection, DMEM/F-12 with 0.15 M extracellular trehalose (hypertonic medium) during microinjection, and
5 DMEM/F-12 with 0.15 M extracellular trehalose (hypertonic medium) after microinjection of 0.15 M trehalose, respectively.

FIG. 11 shows the survival of cooled human oocytes after overnight culture.

FIG. 12A is a graph of a set of curves showing the normalized water volume in oocytes as a function of temperature for different cooling rates. FIG. 12B is a graph showing the calculated dehydration time as a function of temperature. The dehydration time is defined as the time necessary for an oocyte to shrink in volume by 50% at a given temperature.

FIG. 13 is graph of a set of curves showing the cumulative incidence of intracellular ice as a function of temperature in the presence and absence of preservation agents.

FIG. 14 is a table listing the molecular weight and glass transition temperature for sugars with a glass transition temperature greater than -55°C (Levine and Slade, J. Chem. Soc., Faraday Trans. 1, 84:2619-2633, 1988). Many of these sugars are commercially available from sources such as Sigma and British Sugar.

FIG. 15 is a graph showing the monotonic relationship between T_g' and molecular weight of several sugars and traditional cryoprotectants.

FIG. 16 is a bright-field microscopy picture of a microdroplet before and after injection of trehalose solution.

FIG. 17 is a graph of the injection volume (pL) for various injection times (msec) at an injection pressure of 3 PSI for a microdroplet injected with trehalose solution.

FIG. 18 are pictures of fluorescent images of oocytes that have been injected once ("1X") or twice ("2X") with the fluorescent sugar, oregon-green labeled dextran, as described herein.

FIG. 19 is a graph of a standard curve of fluorescent intensity for different concentrations of the OG-labeled dextran within the microdroplets.

DETAILED DESCRIPTION

5 A method for preserving biological tissue of the invention, illustrated in FIG. 1 and FIG. 2, starts with the selection or isolation of the cells or tissue to be preserved (10). While the method of the invention may be used for preservation of any biological material having lipid membranes, it is most useful for preservation of living nucleated cells and, in particular, otherwise difficult to preserve mammalian cells such as oocytes.

Oocytes can be obtained by isolating oviducts and/or ovaries and releasing the oocytes. The oocytes are transferred to hyaluronidase, an enzyme that breaks down extra cells. The oocytes are then washed twice in HEPES-buffered Dulbecco's Modified Eagle Medium/Nutrient F-12 (DMEM/F-12) mixture (Gibco) and BSA (bovine serum albumin). Oocytes are then transferred to modified, isotonic HTF covered with embryo-tested mineral oil (Sigma), or any other suitable medium. The DMEM/F12 media is preferably supplemented with 4 mg/mL BSA. If desired, the oocytes may also be incubated with extracellular sugar at the same concentration as the amount planned for microinjection. For example, to inject 0.1 M sugar, oocytes may be equilibrated in DMEM/F-12 with 0.1 M sugar. As illustrated in Figs. 3A- 3C, the hyperosmoticity of the external DMEM/F-12+ sugar solution causes mouse oocytes to shrink. This decrease in cell volume may be quantitated by visually measuring the diameter of the cells using phase-contrast microscopy. The decrease in cell volume facilitates the determination of how much sugar is subsequently microinjected into the oocytes. For example, the swelling of cells during microinjection to their initial isotonic volume (*i.e.*, the cell volume prior to equilibration with external sugar) indicates that the concentration of injected sugar is close to that of the extracellular sugar concentration (Figs. 3A-3D). Similar results were obtained when human oocytes were incubated in 0.15 M

extracellular trehalose causing their volume to decrease and then injected with trehalose until the volume of the oocytes returned to their initial volume in isotonic media, indicated that 0.15 M trehalose had been injected (Figs. 4A-D).

Alternatively, the oocytes may be optionally equilibrated with any other
5 substantially non-permeable solute, such a NaCl, to decrease their cell volume prior to microinjection. This initial decrease in cell volume may result in a smaller final volume of the microinjected oocytes compared to oocytes not incubated in a hypertonic media prior to microinjection. This smaller final volume may minimize any potential adverse effect from the swelling of the oocytes. This general
10 procedure for the preparation of cells for microinjection may also be used for other cell types.

The target cells are then microinjected (30) with a bio-preservation agent. Microinjection equipment and procedures are well characterized in the art and microinjection equipment known for use in injecting small molecules into cells may
15 be used with the invention. In an exemplary microinjection step, oocytes can be microinjected at a pressure of 10 psi for 30 milliseconds. Another example of a standard microinjection technique is the method described by Nakayama and Yanagimachi (Nature Biotech. 16:639-642, 1998).

For the microinjection of preservation agents, injection pipettes were
20 manufactured from 1-mm borosilicate thin-wall (B100-75-10, Sutter, Novato, CA) glass capillaries. First, the pipettes were pulled using a horizontal micropipette puller (Model P-97, Sutter) such that they had a long shank (~1.3 cm). To obtain a sharp tip with an inside diameter of approximately 0.5 μm , the injection pipettes were beveled at an angle of 40° on a modified Sutter micropipette beveler (BV-10,
25 Sutter) allowing variable rotation speed of the abrasive plate.

If desired, the micropipette used for microinjection of the cryopreservation agent may be calibrated prior to injection (FIG. 5). For this calibration, a microdroplet of DMEM/F-12 medium suspended in a solution of dimethylpolysiloxane was injected with a sugar solution of interest. Preferably, the

microdroplet has a similar size as that of the cells that will be microinjected. For example, microdroplets with a diameter of 70-100 were used to calibrate a micropipette for the microinjection of oocytes. To measure different injection volumes from a given injection pipette, several microdroplets were injected by
5 varying injection time and pressure. Images of each microdroplet were taken using bright-field microscopy before and after injection to calculate the increase in the volume of the droplets and thus the injection volume (Fig. 16). Because the microdroplets are almost perfect spheres, the droplet volumes were reliably calculated using the diameter of the droplets. For example, the volume may be
10 calculated from a cross-sectional image using the formula $V=0.75226 (A)^{3/2}$, where A is the cross sectional area of the microdroplet. In order to determine very small injection volumes, ten consecutive microinjections into a microdroplet were used to produce a measurable volume. This total increase in volume was divided by ten to obtain the average volume per injection. For a given injection pipette, the injection
15 pressure and the pulse duration (*i.e.*, the duration of injection) were two major factors that effected the injection volumes. To calibrate the injection pipettes, the injection pressure was fixed at an appropriate value, and the pulse duration was varied. The injection volume varied linearly as a function of increasing pulse duration (Fig. 17). By varying the pulse duration and collecting enough data
20 points, a slope was generated for a given injection pipette. This slope was particularly useful for choosing different injection volumes for the actual experiments. After calibration, the micropipettes were washed with distilled water by aspirating and blowing out the water. Next, any remaining dimethylpolysiloxane was removed by immersing the micropipettes into methylene chloride (Fisher,
25 Pittsburgh, PA) and then washing the micropipettes with distilled water and pure ethanol. The micropipettes were further prepared for actual cell microinjection by exposing them to vapors of hexamethyldisilazene in a desiccator for several hours to prevent attachment of cell debris to the pipette.

The accuracy of this pre-calibration technique was confirmed using an alternative technique which involved microinjection of Oregon-Green- (OG) labeled dextran (Molecular Probes, Eugene, OR) into oocytes as well as microdroplets. For microinjection of oocytes, 80 μ L of DMEM/F12 medium and 20 μ L of OG-labeled dextran solution (1 mM) prepared in 10 mM Tris (pH 7.4) were placed in a 60X10-mm Falcon plastic culture dish (Fisher) and covered with the mineral oil. Next, oocytes were transferred to the injection drop. Before microinjection, both the holding and the injection pipettes were bended such that their tip portion was horizontal to the focal plane. The holding pipette was filled with the medium and connected to a manual syringe (Sutter) via plastic tubing filled with mineral oil. Similarly, the injection pipette was connected to the Pico Injector via plastic tubing, and the dextran solution was aspirated into the injection pipette. Later, a slight positive balance pressure was applied to the system throughout the microinjection procedure to prevent suction of the outside medium into the injection pipette. During microinjection, an oocyte with the spindle at the 12 or 6 o'clock position was held on the tip of the holding pipette by applying suction via a manual syringe while the injection pipette was inserted into the oocyte from the opposite side. A piezo injector (PM-20, Stoelting) was used to facilitate penetration of the injection pipette by a sudden thrusting movement. Next, the OG-labeled dextran solution was injected into the oocyte using an appropriate time and pressure setting. Similarly, microdroplets of DMEM/F12 medium were injected with the OG-labeled dextran solution using the same time and pressure setting, and the microinjection pipette. After microinjection, fluorescence images of injected oocytes and microdroplets were captured using a Nikon TMD inverted microscope equipped with high pressure mercury arc lamp, fluorescein selective filter set, and a CCD camera. To minimize errors due to possible fluctuations in mercury arc lamp output, each fluorescence image was captured by averaging 64 frames. Fig. 18 depicts typical fluorescence images of oocytes captured after the microinjection as described above. The fluorescence intensity of captured images

was measured on a small spot in the center of the cell or droplet using the Metamorph software package (Universal Imaging Co., West Chester, PA) on a personal computer. Next, a standard curve was generated using different concentrations of the OG-labeled dextran within the microdroplets (Fig. 19). The microinjected dextran concentrations in the oocytes and the microdroplets were estimated using the standard curve. Finally, injection volumes were calculated from the dextran concentrations found in microinjected oocytes and microdroplets. Evaluation of the injection volumes showed that injection into microdroplets reflects injection volumes into oocytes in a sensitivity of pL-range (Fig. 5).

As described earlier, another approach that was also used to determine the concentration of the injected sugar involved comparing the volume of an oocyte in hypertonic medium (*i.e.*, 0.1 M trehalose) before and after microinjection. Because the contribution of 10 mM TRIS to the total osmolarity of the injection buffer (which typically also includes 800 or 1000 mM sugar) is negligible, the re-expansion of the shrunken oocytes in a 0.10 M sugar/medium mixture upon microinjection of sugar can be attributed to the introduction of sugar into the cells. Thus, the extent of the re-expansion after microinjection indicates the intracellular concentration of the injected sugar. Indeed, individual mouse oocytes showed similar volumetric response to the same amount of injected trehalose. Such an experiment is summarized in Figs. 3B-3D which display a typical oocyte at an isotonic volume (Fig. 3B), a shrunken oocyte in hypertonic medium before microinjection of trehalose (Fig. 3C), and a re-expanded oocyte in hypertonic medium after microinjection of trehalose equal to the extracellular trehalose concentration (Fig. 3D).

To achieve a desired cytoplasmic concentration of sugar after microinjection and before any concentration of the intracellular sugar due to freezing or drying of the cell, either the volume of preservation agent that is injected into the cell, the initial concentration of the sugar in the preservation agent, or both can be adjusted. For example, to achieve a relatively high cytoplasmic concentration of sugar after

microinjection, a relatively large volume of preservation agent may be injected or a relatively high concentration of sugar may be injected. Alternatively, if a lower cytoplasmic concentration of sugar is desired, the volume of preservation agent that is injected may be decreased, the concentration of the sugar in the preservation agent may be reduced, or both changes may be made. The volume of preservation agent that is injected may be chosen so that the volume is not so large that the resulting increase in the volume of the cytoplasm causes the cell to lyse.

Additionally, the volume of preservation agent may be chosen so that it is not too small to be accurately measured and injected.

Similarly, to achieve a desired extracellular concentration of sugar after dilution into a liquid medium containing the cell, either the volume of preservation agent that is added to the medium, the initial concentration of the sugar in the preservation agent that is added to the medium, or both can be adjusted. Thus, the extracellular concentration of sugar may be increased by adding a larger volume or a more concentrated solution to the liquid medium. For a preservation agent that is added to a cell grown on a solid medium, such as agar, the desired extracellular sugar concentration can be achieved by contacting the cell with a preservation agent containing sugar at the desired concentration.

A bio-preservation agent useful in this process includes any chemical that has cryo-protective properties and is ordinarily non-permeable. In particular, the bio-preservation agent can include sugars either alone or mixed together with other traditional bio-preservation agents. Carbohydrate sugars such as trehalose, sucrose, fructose, and raffinose, may be microinjected to concentrations less than or equal to about 1.0 M, and more preferably, less than or equal to about 0.4 M. In another preferred embodiment, the concentration is between 0.05 and 0.20 M, inclusive. Additionally, an extracellular sugar or traditional bio-preservation agent may be added prior to storage. If the cells were incubated in a hypertonic solution prior to microinjection, the substantially non-permeable solute may be allowed to remain in

the media after microinjection or may be removed from the media by washing the cells with media containing a lower concentration, or none, of this solute.

5 Certain sugars or polysaccharides which ordinarily do not permeate cell membranes because they are too large to pass through the membrane have superior physiochemical and biological properties for cryopreservation purposes. While these sugars ordinarily do not permeate cell membranes on their own, using the method of the invention, these ordinarily non-permeating sugars may be microinjected intracellularly to result in a beneficial effect.

10 Non-permeating sugars having a stabilizing or preserving effect on cells that are especially useful as the preservation agent in the present method include sucrose, trehalose, fructose, dextran, and raffinose. Among these sugars, trehalose, a non-reducing disaccharide of glucose, has been shown to be exceptionally effective in stabilizing cell structures at low concentrations. Trehalose is the most preferred sugar for use with the present method. It has an exceptional ability to
15 stabilize and preserve proteins, viruses, and bacteria as well as an unusual ability to form stable glasses at high temperatures. Trehalose has physicochemical properties for use as an oocyte cell cryoprotective agent (CPA) that are far superior to traditional agents. Further, trehalose, contained in many food products, is relatively non-toxic and may allow for cryopreservation protocols which do not require CPA
20 removal, resulting in an infusible end product. Sucrose, which has properties similar to those of trehalose and which is widely available and relatively inexpensive, may also be preferred for certain applications. There are also advantages to using dextran either alone or in combination with other sugars, such as trehalose or sucrose. Dextran has a very high glass transition temperature (T_g'),
25 but does not have some of the advantages that are present in sucrose or trehalose, such as the ability to stabilize biological components. Thus, a dextran trehalose mixture, or dextran sucrose mixture, may have added benefits.

The addition of extracellular glycolipids or glycoproteins may also stabilize the cell membrane. While not meant to limit the invention to any particular theory, it is hypothesized that the sugar groups in glycolipids may hydrogen-bond with the hydrophilic head groups of membrane phospholipids, stabilizing the membrane against freezing-induced stress. Additionally, it is possible that the glycolipids may be incorporated into the lipid bilayer and increase the integrity of the membrane.

Following the microinjection of the preservation agent, the cells are prepared for storage 40. A variety of methods for freezing and/or drying may be employed to prepare the cells for storage. In particular, three approaches are described herein: vacuum or air drying 50, freeze drying 60, and freeze-thaw 70 protocols. Drying processes have the advantage that the stabilized biological material may be transported and stored at ambient temperatures.

FIG. 6 shows a phase diagram of a conventional penetrating cryoprotectant (DMSO) versus a common sugar (trehalose). Typically, oocytes loaded with 1 to 2M DMSO are cooled at a very slow cooling rate (0.3 to 0.5°C/min) to an intermediate temperature (-60°C to -80°C) before plunging in liquid nitrogen for storage. As a result of the slow cooling rate, oocytes have ample time to dehydrate and closely follow the equilibrium melting curve (T_m) of the cryoprotectant solution (e.g., DMSO) down to a temperature range between -30°C and -50°C. Since the permeability of the plasma membrane to water decreases exponentially as a function of decreasing temperature at temperatures below -50°C, the cellular dehydration becomes negligible for any practical purposes. As the temperature is further decreased to the storage temperature, the unfrozen solution inside the oocytes becomes more concentrated until the temperature reaches the T_g curve at the point T_g' , and then the solution becomes glass. As a result, the fraction of the cellular water which remains in the cell, crystallizes during further cooling to the storage temperatures (typically below the glass transition temperature, T_g'). The formation of ice inside the cells is believed to result in cell death if the fraction of cellular water transformed to ice phase surpasses a certain limit (usually 5%). On

the other hand, the phase diagram of trehalose is such that T_m and T_g curves cross each other at a very high subzero temperature (approximately -30°C) compared to DMSO (approximately -80°C). As a result, one can freeze the oocyte, and dehydrate very close to its glass transition temperature while the membrane water permeability is still high, and thereafter plunge in liquid nitrogen to vitrify the sample. The sample can then be stored at this temperature. This process enables oocytes to overcome the so-called "bottle-neck" effect observed below -50°C with most conventional penetrating cryoprotectants. Beneficial results may also be obtained by applying extracellular sugars, in addition to the intracellular sugars, to the cell.

The suspended material can then be stored 90, 100 at cryopreservation temperatures, for example, by leaving the vials in LN_2 , for the desired amount of time. Preferably, the cells are stored at a temperature equal to or less than the T_g' of the cryoprotectant so that the cells remain in the glassy state. Preferred storage temperatures are at least 5, 10, 15, 20, 30, or 40°C below the T_g' . The cells are also preferably maintained at a relatively constant temperature during storage. Preferably, the storage temperature changes by less than 20, 10, 5, or 3°C during storage. The suspended cells can then be recovered from storage 110 by thawing 120 in a 37°C water bath with continuous, mild agitation for 5 minutes.

Protocols for vacuum or air drying 50 and for freeze drying 60 proteins are well characterized in the art [Franks et al., "Materials Science and the Production of Shelf-Stable Biologicals," *BioPharm*, October 1991, p. 39; Shalaev et al., "Changes in the Physical State of Model Mixtures during Freezing and Drying: Impact on Product Quality," *Cryobiol.* 33, 14-26 (1996).] and such protocols may be used to prepare cell suspensions for storage with the method of the invention. In addition to air drying, other convective drying methods that may be used to remove water from cell suspensions include the convective flow of nitrogen or other gases. In

one preferred embodiment, the gas used for convective drying does not contain oxygen which may be deleterious to certain cells.

5 An exemplary evaporative vacuum drying protocol 130 useful with the method of the invention may include placing 20 μ l each into wells on 12 well plates and vacuum drying for 2 hours at ambient temperature. Of course, other drying methods could be used, including drying the cells in vials. Cells prepared in this manner may be stored dry 140, and rehydrated 160 by diluting in DMEM or any other suitable media.

10 A method of the invention using freeze drying 60 to prepare the cells for storage 40 begins with freezing 80 the cell suspension. While prior art freezing methods may be employed, the simple plunge freezing method described herein for the freeze-thaw method may also be used for the freezing step 80 in the freeze drying protocol.

15 After freezing, a two stage drying process 150 may be employed. In the first stage, energy of sublimation is added to vaporize frozen water. When freeze drying cells, the primary criterion for selecting the temperature of the primary drying phase is that it must be below the glass phase transition temperature of the freeze concentrated solution to avoid collapse and undesirable chemical reactions. In general, the highest possible temperature that will not damage the sample should be used so that sublimation will occur quickly. Typically, the primary drying occurs at 20 a constant temperature maintained below the glass transition temperature for the freeze concentrated solution.

25 Secondary drying is performed after the pure crystalline ice in the sample has been sublimated. Secondary drying cannot take place unless the temperature is raised above the glass phase transition temperature of the freeze concentrated solute, however, it is crucial that the sample temperature does not rise above the collapse temperature above which the specimen is believed to mechanically collapse due to viscous flow.

Freeze dried cells can be stored 140 and hydrated 160 in the same manner as described above for vacuum drying. Viable cells may then be recovered 170.

After the recovery of cells from a frozen or dried state, any external cyropreservation may be optionally removed from the culture media. For example, 5 the media may be diluted by the addition of the corresponding media with a lower concentration of cyropreservation agent. For example, the recovered cells may be incubated for approximately five minutes in media containing a lower concentration of sugar than that used for cell storage. For this incubation, the media may contain the same sugar that was used as the cyropreservation agent; a different 10 cryopreservation agent, such as galactose; or any other substantially non-permeable solute. To minimize any osmotic shock induced by the decrease in the osmolarity of the media, the concentration of the extracellular cyropreservation agent may be slowly decreased by performing this dilution step multiple times, each time with a lower concentration of cyropreservation agent (FIG. 2). These dilution steps may 15 be repeated until there is no extracellular cyropreservation agent present or until the concentration of cyropreservation agent or the osmolarity of the media is reduced to a desired level.

For cells that divide relatively quickly, such as fibroblasts, the internal concentration of sugar quickly decreases as the sugar is divided between the mother 20 and daughter cells. Thus, the internal osmolarity of the cells may decrease to a level close to that of a traditional isotonic media, enabling the recovered cells to be cultured in an isotonic media without significant swelling or adverse effects caused by a difference between the internal and external osmolarity of the cells.

For culturing recovered cells that do not divide or that divide slowly, such as 25 oocytes, using a hypertonic media may prevent or reduce the swelling of the cells that might otherwise occur if they were returned to an isotonic media. Thus, a hypertonic media for the culturing of certain recovered cells was developed using a two-prong approach. First, a standard culture medium called HTF (human tubal fluid medium) was modified to minimize the concentration of electrolytes (see FIG.

7, components marked with down arrows) and to increase other nutrients and amino acids (see FIG. 7, components marked with up arrows). The osmolarity of this medium was determined using an osmometer. Because the osmolarity of this medium was approximately 285 mosm, which is close to the normal internal
5 osmolarity of cells, this medium is called modified HTF, isotonic. Second, the water content of the medium was reduced to equally increase the concentrations of each component to achieve a final osmolarity of 320 mosm. This medium is called modified HTF, hypertonic, (see FIG. 7, last column).

To test the ability of modified HTF, isotonic and hypertonic media to
10 support the fertilization and development of oocytes, these medias were used to culture fresh mouse metaphase II oocytes that had not been cryopreserved. As illustrated in FIG. 8, control mouse oocytes without intracellular trehalose cultured in either modified HTF, isotonic or modified HTF, hypertonic media had a high frequency of fertilization (90%) and development to blastocyst-stage (over 85%).
15 Mouse oocytes injected with 0.07M trehalose also showed a high frequency of fertilization and blastocyst development in modified HTF, hypertonic media. At an intracellular trehalose of 0.15 M, the frequencies of fertilization and blastocyte formation were reduced, but still significant. If desired, the composition and hypertonicity of the culture medium may be further optimized to increase the
20 number of blastocysts or viable offspring that are formed. For example, a culture medium having a higher osmolarity (such as 330, 340, 350, 360, 370, or 380 mosm) may better mimic oviductal fluid (which may have an osmolarity of at least 360 mosm) and thus further promote development of viable offspring (Van Winkle *et al.*, J. Expt Zool. 253:215-219, 1990). Any other suitable hypertonic media with a
25 osmolarity of at least 300, 310, 320, 330, 340, 350, 360, 370, 380, or more mosm may be used in preferred methods for culturing cells *in vitro*. These methods may be used to culture cells with or without intracellular sugar. These preferred medias may also be used before, during, or after storage of cryopreserved cells.

Figures 9A and 9B are a set of graphs showing the survival of cooled metaphase II mouse oocytes after overnight culture in modified HTF, hypertonic media as a function of extracellular trehalose concentration at -15° and -30° , respectively. These experiments were performed using a cooling rate of $1^{\circ}\text{C}/\text{min}$,
5 with or without approximately 0.10 to 0.15 M intracellular trehalose. Cell viability was assessed using the live/dead assay described herein. Additionally, light microscopy was used to visually determine whether the viable oocytes had an intact membrane and lacked signs of degeneration and fragmentation. At both -15 and -30°C , the addition of approximately 0.10 to 0.15 M trehalose inside oocytes
10 dramatically increased the survival rate. Furthermore, at -30°C , the absence of internal trehalose resulted in few viable oocytes after freezing. The amount of extracellular trehalose had a dramatic, dose-dependent effect on survival. As the extracellular amount of trehalose in the freezing solution was increased from 0.15 M (approximately the same amount as the intracellular trehalose) to 0.30 M or
15 0.50 M, the survival rate improved from about 18, to 55 or 85%, respectively. This result shows the benefit of using both internal and external cryopreservation agents during cooling of cells.

FIG. 10 shows the survival of cooled metaphase II mouse oocytes after overnight culture in modified HTF media, isotonic. FIG. 11 shows the survival of
20 cooled human oocytes after overnight culture in HTF media plus 0.1 M extracellular trehalose. Cell survival was measured using the live/dead assay. Light microscopy was also used to visually determine whether the viable oocytes had an intact membrane and lacked signs of degeneration and fragmentation. The bracket labeled Tg' in FIG. 10 and FIG. 11 shows possible long-term storage temperatures
25 when trehalose is present both intra- and extracellularly. In FIG. 10, oocytes were cooled at a very slow cooling rate to an intermediate temperature (-60°C). Oocytes with no trehalose resulted in a 0% survival rate. Oocytes loaded with 0.50M extracellular trehalose experienced some improvement over the control, but suffered a steady decrease in the survival rate as the temperature decreased.

Oocytes loaded with 0.15M intracellular and 0.50M extracellular trehalose, on the other hand, maintained a survival rate between 80 and 100%. In comparison with the control and with oocytes in an extracellular trehalose solution, oocytes containing intracellular trehalose experienced a significant increase in survival rate.

5 FIG. 12A is a graph with multiple curves that illustrate the water content of mouse oocytes as a function of temperature for different cooling rates, based on the following well-established equations for the rate of water transport during freezing (Karlsson *et al.*, Human Reproduction 11:1296-1305, 1996; Toner *et al.*, J. of Membrane Biology 115:261-272, 1990).

10

$$\frac{dV}{dT} = \frac{LpRT}{Bv_w} A(\ln a_w^{ex} - \ln a_w^{in})$$

where R is the gas constant; T is the temperature; B is the cooling rate; v_w is the partial molar volume of water, and a_w^{ex} and a_w^{in} are the water activities in the external and intracellular solutions, respectively. Lp is the water permeability given by

15

$$Lp = Lpg \exp\left[-\frac{ELp}{R}\left(\frac{1}{T} - \frac{1}{T_R}\right)\right]$$

where Lpg is the reference water permeability at T_R ; ELp is the activation energy or temperature dependence of water permeability, and T_R is the reference temperature (typically, 0°C).

As illustrated in these curves, the extent of dehydration of oocytes depends on the cooling rate. For example, very slow cooling rates may result in excess dehydration of oocytes. Alternatively, very fast cooling rates (e.g. 30 or 60°C/min), may result in minimal dehydration. Thus, intermediate cooling rates, such as those between 0.1 and 5°C/min, are preferable. For these rates, the water

20

transport model predicts that the intracellular water volume will initially decrease and then asymptotically approach a constant value. As illustrated in this figure, water permeability is an exponential function of temperature with an activation energy, EL_p , of 14.5 kcal/mol for mouse oocytes. Thus, as the temperature is lowered
5 during freezing, L_p decreases precipitously and reaches almost zero for temperatures below $-50^{\circ}\text{C}/\text{min}$. Due to the similarities between the temperature dependence of L_p (*i.e.*, the value of EL_p) for mouse oocytes and oocytes from other mammals, such as rats, bovine, and humans, similar dehydration behavior is expected for other oocytes. For example, EL_p is 14.70 kcal/mol for human
10 oocytes, compared to 14.5 kcal/mol for mouse oocytes (Paynter *et al.*, Human Reproduction 14: 2338-2342, 1999).

FIG. 12B is a graph that illustrates the calculated dehydration time necessary for the volume of an oocyte to be reduced by 50% at a given temperature. This graph was generated using the water transport equations listed above and clearly
15 indicates that water transport is significantly reduced at low temperatures, especially at temperatures below -50°C . Thus, cells are preferably cooled using the methods of the invention to a final temperature of at least -50 , -40 , -30 , -20 , or -10°C to allow dehydration to continue at a significant rate. After dehydration is complete, the cells may be stored at this temperature or at a lower temperature to
20 maintain the cells in a glass state until they are needed.

FIG. 13 is a graph with a set of curves showing the percentage of oocytes that have intracellular ice at various temperatures. For this assay, standard cryomicroscopy procedures were used to cool oocytes at a rate of $3.5^{\circ}\text{C}/\text{min}$ (Cosman *et al.*, Cryo-Letters 10:17-38, 1989). The oocytes were observed using a
25 cryomicroscope to determine whether intracellular ice had formed. The presence of intracellular ice was easily detected based on the black color that appeared due to the light scattered by the ice crystals. This assay was used to test control oocytes incubated in isotonic media alone, oocytes incubated in media with 0.1 M extracellular trehalose, and oocytes injected with 0.1 M trehalose and incubated in

media with 0.1 M extracellular trehalose. As illustrated in FIG. 13, extracellular trehalose reduced the incidence of intracellular ice formation in oocytes. The frequency of intracellular ice was further reduced by the presence of intracellular trehalose in addition to the extracellular trehalose. If desired, the amount of intracellular ice may be further reduced by increasing the concentration of intracellular or extracellular sugar that is used. The ability of trehalose to significantly reduce internal ice allows faster cooling rates. In the field of cryobiology, it has been established that the faster the cooling rate without formation of lethal intracellular ice, the greater the chance of cell survival.

FIG. 14 is a table that lists sugars with a glass transition temperature of greater than -55°C . As illustrated in this table, sugars with higher molecular weights tend to have higher glass transition temperatures. Linear polymers also tend to have higher glass transition temperatures than branched polymers of the same molecular weight. Comparing linear and cyclic α -(1 \rightarrow 4)-linked glucose hexamers, a cyclic oligomer (cyclodextrin, $T_g' = -9^{\circ}\text{C}$) had a higher glass transition temperature than a linear oligomer (maltohexaose, $T_g' = -14.5^{\circ}\text{C}$) (Levine and Slade, *supra*).

A graph of T_g' as a function of molecular weight for some sugars and traditional cryoprotectants is shown in FIG 15. In a more comprehensive figure in Levine and Slade (*supra*) for 84 small sugars, the monotonic relationship between increasing T_g' and molecular weight yielded a linear correlation of $r = -0.93$. Thus, for sugars with a molecular weight of at least 120 daltons, their T_g' is at least -50°C .

OTHER EMBODIMENTS

From the foregoing description, it will be apparent that variations and modifications may be made to the invention described herein to adopt it to various usages and conditions. Such embodiments are also within the scope of the following claims.

All publications mentioned in this specification are herein incorporated by reference to the same extent as if each independent publication or patent application was specifically and individually indicated to be incorporated by reference.

5 What is claimed is:

1. A method for treating a living cell, said method comprising the steps of:
 - (a) microinjecting into the cytoplasm of said cell a protective agent which (i) comprises a sugar, (ii) is substantially non-permeating with respect to mammalian cell membranes, and (iii) maintains the viability of said cell such that it can be
5 stored in a temporarily dormant state and substantially restored to an active state;
 - (b) treating said cell to cause it to enter said dormant state; and
 - (c) storing said cell in said dormant state.
2. The method of claim 1, further comprising the step of (d) treating said
10 cell to restore it to an active state.
3. The method of claim 1, wherein said cell is a mammalian cell.
4. The method of claim 3, wherein said cell is an oocyte.
15
5. The method of claim 3, wherein said cell is an epithelial cell, neural cell, epidermal cell, keratinocyte, hematopoietic cell, melanocyte, chondrocyte, B-cell, T-cell, erythrocyte, macrophage, monocyte, fibroblast, muscle cell, embryonic stem cell, or adult stem cell.
20
6. The method of claim 1, further comprising contacting said cell with an extracellular protective agent that is substantially non-permeating with respect to mammalian cell membranes and that stabilizes the cell membrane of said cell.
- 25 7. The method of claim 1, wherein said protective agent comprises at least one sugar selected from the group consisting of sucrose, trehalose, fructose, dextran, and raffinose.

8. The method of claim 1, wherein said protective agent comprises at least one sugar selected from the group consisting of glucose, sorbitol, mannitol, lactose, maltose, and stachyose.

5 9. The method of claim 1, wherein said protective agent comprises at least one sugar with a glass transition temperature greater than -50°C .

10 10. The method of claim 9, wherein said protective agent comprises at least one sugar with a glass transition temperature greater than -30°C .

11. The method of claim 1, wherein said protective agent comprises at least one sugar with a molecular weight greater than 120 daltons.

15 12. The method of claim 1, wherein said protective agent comprises at least one sugar with a glass transition temperature greater than -30°C and a molecular weight greater than 120 daltons.

20 13. The method of claim 1, wherein said protective agent comprises a glycolipid or a glycoprotein that comprises at least one sugar moiety derived from a sugar with a glass transition temperature greater than -50°C .

14. The method of claim 1, wherein the cytoplasmic concentration of said sugar is less than or equal to about 1.0 M following step (a) and prior to step (b).

25 15. The method of claim 14, wherein the cytoplasmic concentration of said sugar is less than or equal to about 0.2 M following step (a) and prior to step (b).

16. The method of claim 6, wherein said extracellular protective agent comprises an extracellular sugar.

17. The method of claim 16, wherein said cell is maintained in a liquid medium, and wherein the extracellular concentration of said extracellular sugar is less than or equal to about 1.0 M following dilution into said liquid medium.

5 18. The method of claim 17, wherein the extracellular concentration of said extracellular sugar is less than or equal to about 0.2 M following dilution into said liquid medium.

10 19. The method of claim 16, wherein said cell is maintained on a solid medium, and wherein the concentration of said extracellular sugar is less than or equal to about 1.0 M following administration to said cell.

15 20. The method of claim 19, wherein the concentration of said extracellular sugar is less than or equal to about 0.2 M following administration to said cell.

 21. The method of claim 1, wherein step (b) comprises freezing said cell to a cryogenic temperature.

20 22. The method of claim 21, wherein said cell is plunge frozen.

 23. The method of claim 21, wherein said cell is cooled at a rate between 0.3 and 6°C per minute to a final temperature that is at least -50°C.

25 24. The method of claim 23, wherein said cell is at a rate between 0.3 and 3°C per minute to a final temperature that is between -50 and -10 °C.

 25. The method of claim 21, wherein step (d) comprises thawing said cell.

26. The method of claim 1, wherein step (b) comprises drying said cell to a level sufficient to permit dry storage.

5 27. The method of claim 26, wherein step (b) comprises freeze drying said cell.

28. The method of claim 26, wherein step (b) comprises vacuum or convective drying said cell.

10 29. The method of claim 26, wherein step (d) comprises rehydrating said cell.

30. The method of claim 1, wherein only said protective agent is employed.

15 31. The method of claim 1, wherein prior to step (a), said cell is maintained in a hypertonic medium having an osmolarity greater than 300 mosm.

32. The method of claim 2, wherein following step (d), said cell is cultured in a hypertonic medium having an osmolarity greater than 300 mosm.

20

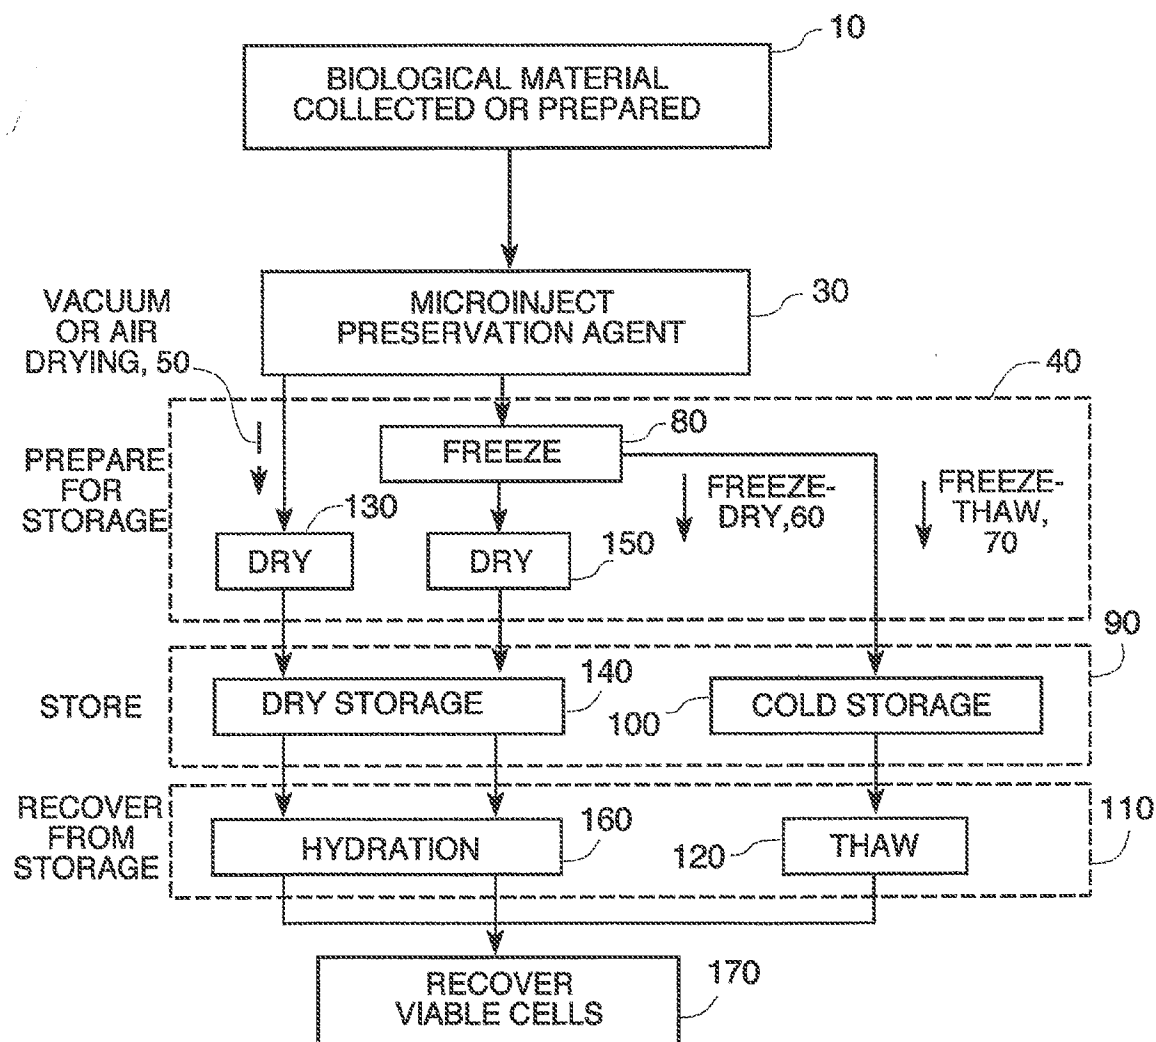

33 The method of claim 1, wherein a penetrating cryoprotectant mixture is added to said preservation agent.

25 34. A method of culturing a cell *in vitro*, comprising incubating said cell in a hypertonic medium having an osmolarity greater than 300 mosm.

35. The method of claim 34, wherein the osmolarity of said medium is greater than 320 mosm.

quinovose (deoxyglucose)	164.2	-43.5
fucose (deoxygalactase)	164.2	-43
rhamnose (deoxymannose)	164.2	-43
talose	180.2	-44
idose	180.2	-44
psicose	180.2	-44
altrose	180.2	-43.5
glucose	180.2	-43
gulose	180.2	-42.5
fructose	180.2	-42
galactose	180.2	-41.5

FIG. 14A

15/22

Solute	M _w	T _g °C
allose	180.2	-41.5
sorbose	180.2	-41
mannose	180.2	-41
tagatose	180.2	-40.5
inositol	180.2	-35.5
mannitol	182.2	-40
galactitol	182.2	-39
sorbitol	182.2	-43.5
2- <i>O</i> -methyl fructoside	194.2	-51.5
β-1- <i>O</i> -methyl glucoside	194.2	-47
3- <i>O</i> -methyl glucoside	194.2	-45.5
6- <i>O</i> -methyl galactoside	194.2	-45.5
α-1- <i>O</i> -methyl glucoside	194.2	-44.5
1- <i>O</i> -methyl galactoside	194.2	-44.5
1- <i>O</i> -methyl mannoside	194.2	-43.5
1- <i>O</i> -ethyl glucoside	208.2	-46.5
2- <i>O</i> -ethyl fructoside	208.2	-46.5
1- <i>O</i> -ethyl galactoside	208.2	-45
1- <i>O</i> -ethyl mannoside	208.2	-43.5
glucoheptose	210.2	-37.5
mannoheptulose	210.2	-36.5
glucoheptulose	210.2	-36.5
perseitol (mannoheptitol)	212.2	-32.5
1- <i>O</i> -propyl glucoside	222.2	-43
1- <i>O</i> -propyl galactoside	222.2	-42

FIG. 14B

16/22

Solute	M _w	T _g °C
1-O-propyl mannoside	222.2	-40.5
2,3,4,6-O-methyl glucoside	236.2	-45.5
isomaltulose (palatinose)	342.3	-35.5
